(54) Method of printed circuit panel manufacture.

(57) Disclosed is a method of manufacturing a printed circuit panel. The method is carried out without a cleanroom, but in a clean room environment. The first step is to place a thin, non-rigid panel in a suitable fixture system, for example, for transfer and also for processing. The system includes a peripheral frame fixture for surrounding and supporting the in-process circuit panel layer, and a loading chuck for mounting the in-process circuit panel layer in the peripheral frame fixture. The peripheral frame fixture includes a bottom plate (175) having a central opening to expose the circuit panel layer, a top frame (179) having a corresponding central opening to expose the opposite surface of the circuit panel layer, and compressive means, as screws, bolts, or the like, for applying a z-axis compressive force to the bottom plate, the top frame, and a panel layer therebetween. The loading chuck includes a peripheral edge for receiving the bottom plate of the peripheral frame fixture.

A vacuum table is within the area bounded by the peripheral edge of the loading chuck and the peripheral frame of the peripheral frame fixture, and is coplanar with them. The vacuum table includes slidable bearing surfaces (131), with vacuum apertures (133) for drawing a vacuum to hold the panel in place, and slide actuators for moving the slidable bearing surfaces to apply x-y-axis tension to a panel on the bearing surfaces.

The fixtured panel is then placed in an air tight transfer container, which has a substantially contaminant free atmosphere. The walls of the transfer container are fabricated out of substantially particulate free, unfilled polymers, such as polycarbonate. One of the end walls is an access wall. The access wall has an opening surrounded by a ferromagnetic gasket. This gasketed opening is adapted to receive a ferromagnetic door panel. The transfer container has a sealed door at one end. The transfer container is then brought into a sealable,

EP 0 574 893 A2

substantially airtight interlock with a process enclosure. This process enclosure also has a substantially contaminant free atmosphere, and a sealed door at one end. An airtight seal is formed between the transfer container and the process enclosure, and also between the surfaces of the two doors. This is to avoid introducing surface contaminants into the process enclosure and transfer container atmospheres. Next, the two doors are opened simultaneously. This is to allow the transfer of at least one panel and its fixture from the transfer container into the process enclosure. Inside the process enclosure the panel is transferred to a process station for a manufacturing process. Finally, the panel and its fixture are transferred from the process enclosure into the transfer container. This may be the same container or a different container. The doors of the process enclosure and the transfer container are then closed and sealed. Also disclosed is a manu-

facturing system having isolated islands of "clean room" environment connected by inter-process transfer containers for transferring in-process workpieces. The system has airlock transfer ports between the process enclosures and the inter-process transfer containers. The make and break airlock transfer ports have facing sealable doors in the process enclosure and the transfer container. These doors are in air sealable facing recesses of the process enclosure and the transfer container. At least one peripheral gasket surrounds the recesses and the pair of doors. This provides a substantially clean room environment in the airlock. The sealable door in the interprocess transfer container is fabricated of a ferromagnetic material and is seated on a ferromagnetic gasket, while the sealable door in the process enclosure has a controllable electromagnetic clamp.

The invention relates generally to the manufacture of circuit panels, as circuit cards and circuit boards, including individual layers thereof, and more particularly to the manufacture of layers, cards, boards, and panels under clean room conditions, but without a clean room. The manufacturing processes are carried out in process enclosures that are isolated islands of clean room atmosphere, connected by interprocess transfer containers.

One aspect of the invention described herein is a method of manufacturing a printed circuit panel where a thin, non-rigid panel is fixtured. The fixture, including the thin panel, is placed in an air tight transfer container which has a substantially contaminant free atmosphere, and a sealed door at one end. The transfer container is brought into a sealable, substantially airtight interlock with a process enclosure. The process enclosure also has a substantially contaminant free atmosphere, and a sealed door at one end.

An airtight seal is formed between the transfer container and the process enclosure, and the surfaces of the two doors are isolated so as to avoid introducing surface contaminants into the process enclosure and transfer container atmospheres. The doors are then simultaneously opened.

After the doors are opened, at least one panel and its fixture are transferred from the transfer container into the process enclosure. The panel is robotically transferred to a process station inside the process enclosure, and processed. After processing, the panel and its fixture are robotically transferred from the process enclosure into the transfer container. The doors of the process enclosure and the transfer container are then closed, and the transfer container removed.

Another aspect of the invention described herein is a container for carrying circuit panels in a substantially contaminant free environment, and between substantially contaminant free environments. The container is a walled container having a pair of parallel side walls, a pair of parallel end walls, a top, and a bottom. The container is fabricated of a substantially particulate free, unfilled, polycarbonate to avoid introduction of filler materials into the clean room environment of the process enclosures or the transfer container.

One of the end walls is an access wall having an opening surrounded by a ferromagnetic gasket. The end wall and gasket are intended to receive a ferromagnetic door panel. Each of the side walls has co-planar bracket pairs for holding circuit panels.

According to another aspect of invention the process enclosure and the inter-process transfer container have an interlock for transferring panels, for example, in-process panels, without breaking

clean room conditions. The interlock starts with facing sealable doors in the process enclosure and the transfer container.

The sealable doors are in air sealable facing recesses of the process enclosure and the transfer container. At least one peripheral gasket surrounds the recesses and the pair of doors to provide a substantially clean room environment in the airlock. The sealable door in the process enclosure is moved by a controllable electromagnetic clamp. This clamp clamps the ferromagnetic transfer container door. There is a ferromagnetic gasket between the sealable, ferromagnetic door in the inter-process transfer container and the process container. This provides a magnetic seal between the ferromagnetic door of the interprocess transfer container and the ferromagnetic door thereof.

Upon actuation, the electromagnetic clamp in the process enclosure door magnetically attracts the container's ferromagnetic door and pulls it away from the ferromagnetic gasket. After the ferromagnetic door is clamped by the electromagnet, the process container door and the transfer container door are simultaneously opened.

Still another aspect of the invention described herein is a system for handling large area, flimsy, in-process, circuit panel layers. The elements of the system are a peripheral frame fixture for surrounding the panel layer, and a loading chuck for mounting the panel layer in the peripheral frame fixture.

The peripheral frame fixture for surrounding the panel layer includes a bottom plate having a central opening, a top frame having a central opening, and compressive means for applying a z-axis compressive force to the bottom plate, the top frame, and the panel layer between plate and the frame. The bottom plate and top frame apply both a z-axis compressive force on the surfaces of the panel layer and x-y axis tensile forces to the panel.

The loading chuck for mounting the panel layer in the peripheral frame fixture has a peripheral edge for receiving the bottom plate of the peripheral frame fixture, and a vacuum table within the area bounded by the peripheral edge of the loading chuck and the peripheral frame of the peripheral frame fixture. The loading chuck is substantially coplanar with the panel layer. The vacuum table includes a plurality of slidable bearing surfaces. The bearing surfaces having vacuum apertures for drawing a vacuum to hold a panel against the bearing surface. The vacuum table also includes slide actuators for moving the slidable bearing surfaces to apply x-y-axis tension to a panel on the bearing surfaces. A further aspect of the vacuum table are the vacuum holes for applying a vacuum to the slidable bearing surfaces.

As dimensions shrink and circuit densities increase in circuit board and card manufacturing, the problems heretofore associated with and limited to IC manufacture are now increasing relevant to circuit board and card manufacture. For example, Class-100K and 10K cleanrooms are typically used in card and board manufacturing. Circuit cards and boards are 10" by 15", and even 24" by 28", and larger, with thickness of 25-125 μm (1-5 mils), 50 μm (2 mil) feature sizes, and circuit densities that result in 3.05 m or more (ten or more linear feet) of Cu wiring per square inch of card or board surface.

In this 50 μm (2 mil) and smaller geometry environment, a dust particle that would have gone unnoticed in a 100 μm (4 mil) geometry environment can result in incomplete etching during subtractive circuitization resulting in an electrical open.

A small volume of still, particle free air, with no internal (local) source of particles is the cleanest possible environment for high circuit density circuit card and board manufacturing.

A small volume of still, particle free air, with no internal (local) source of particles is attained in the silicon semiconductor wafer industry by the SMIF (Standard Mechanical Interface) system. SMIF provides a movable sealable container and a series of small work volumes. The SMIF system includes means for loading and unloading the container, means for placing the wafers (and wafer cassettes) into and removing the wafers (and wafer cassettes) from an individual work volume, and a canopy to seal the movable sealable container and the work volume during transfer. Finally, the SMIF system includes work volume air processing means.

SMIF reduces the need for (1) costly, large volume air handling, and (2) temperature and humidity control.

U.S. Patent 4,963,069 to Thomas Kahlden, Rudolf Simon, and Manfred Wurst for CONTAINER FOR THE HANDLING OF SEMICONDUCTOR DEVICES AND PROCESS FOR PARTICLE-FREE TRANSFER describes a container and transfer process are intended to prevent contamination of wafer scale semiconductor devices from occurring, even when the wafer container is stored or handled under unclean room conditions. The wafers inside the container are subjected to an approximately laminar clean air stream passing around them in a clean air zone. A higher static pressure is maintained in the clean air zone than in the surrounding space. The surrounding space is subject to pollution with an inadmissibly high number of particles. The clean air stream carries along any dirt particles there may still be, so that these dirt particles cannot settle on the semiconductor devices. As a result of the higher static pressure, a forced flow

from the clean air zone of the higher static pressure outwards into the surrounding space is achieved. This prevents entry of dirt particles from the surrounding space.

U.S. Patent 4,815,912 to George W. Faraco, George A. Maney, and Mihir Parikh for BOX DOOR ACTUATED CONTAINER describes a transportable container for wafers in-process. The container is designed for use with passage elevator means for passing the wafer cassettes between work station locations. The container includes the body member, an opening in the body member, an airlock door across the opening, and a wafer cassette. The wafer cassette is supported by the door and sized for passage through the door. Passage of the wafer cassette downward through open door is effected by an elevator.

United States Patent 4,739,882 to Anthony C. Bonora, George Faraco, Barney H. Huang, and Mihir Parikh for CONTAINER HAVING DISPOSABLE LINERS describes a transportable container for storing articles, such as wafers, while maintaining the articles clean. The container utilizes a liner that is insertable into the interior space and surrounds the contents. The wafer cassette wafers are supported by the container door.

United States Patent 4,724,874 to Anthony C. Bonora and Mihir Parikh for SEALABLE TRANSPORTABLE CONTAINER HAVING A PARTICLE FILTERING SYSTEM describes a sealable transportable container for use with semiconductor wafer processing equipment. The container is a double container, with an inner container and an outer container. The outer container has a port plate with a port door sealably mating to the port plate. Inside of the outer transportable container is an inner container, referred to as a box. This box has an interior space for containing the wafer cassettes. The box has a conduit for communicating between its interior space and the environment external to the box, i.e., the surrounding fabrication facility. The conduit has a filter for filtering fluids, i.e., air, passing through the conduit. The box is a sealed box with a box top having sealing surfaces and a box door sealably mating with the box top.

The port plate also includes sealing surfaces and is sealably mated to the box top. The port door has a sealing surface and is sealably mated to the port plate. The inner or box door includes a latch for mechanically opening and closing of the box. The outer or port door includes a device for activating the latch on the inner or box door.

U.S. Patent 4,995,430 to Anthony C. Bonora and Frederick C. Rosenquist for SEALABLE TRANSPORTABLE CONTAINER HAVING IMPROVED LATCH MECHANISM describes a transportable, sealable container, such as a SMIF (Standard Mechanical Interface) pod, with an outer

box and box door. The box has a first sealing surface and the box door has a second sealing surface. These sealing surfaces form a seal when the box door is moved in a sealing direction with respect to the box.

A latch mechanism is provided in the box door. This latch mechanism is operable in two stages. The first stage of operation moves the latch members from a retracted position to an extended position. In the retracted position the latch members are in the box door so as to allow movement of the box door with respect to the box.

In the extended position the latch members are adjacent to latch surfaces of the box. Movement from the retracted to the extended position is performed without contact between the latch members and the latch surfaces. This avoids any scraping or rubbing action which would create particles in the "clean" interior region of the box.

The second stage of operation engages latch members with the latch surfaces to move the box door in the sealing direction; this second stage of the operation is also performed without scraping or rubbing of the latch members and the latch surfaces.

United States Patent 4,674,939 for George Faraco, George A. Maney, and Andrew W. O'Sullivan for SEALED STANDARD INTERFACE APPARATUS describes a partitioned container apparatus for keeping workpieces, such as semiconductor wafers, clean during a fabrication sequence. The container is used to transport the wafers to and between ports in the canopies of the processing equipment.

The container has first and second regions for making first and second seals. A container door seals the workpieces into the box. The container has a second region for making the second seal and has a third region for making a third seal.

The processing equipment canopy ports are adapted for receiving the container and container door and for transferring the container door and the container contents into a region of the processing equipment beneath the canopy. The canopy has a first region for making the first seal with the container. Also, the canopy has a fourth region surrounding the port for making a fourth seal.

A port door is provided for closing the canopy port when no container is present. The port door has a second region for making the second seal with the container and has a fourth region for making the fourth seal with the canopy.

A container door latch is provided for latching the container door to the container so that the second seal is made and released in the second region between the container door and the container by operation of the container door latch.

A container latch is provided for latching the container to the canopy so that the first seal is made or released in the first region between the container and the canopy by the operation of the container latch.

U.S. Patent 4,616,683 to Mark E. Johnston, Mihir Parikh, David L. Thrasher, and Barclay J. Tullis for PARTICLE-FREE DOCKABLE INTERFACE FOR INTEGRATED CIRCUIT PROCESSING (A continuation of U.S. Patent No. 4,532,970) describes a particle-free dockable interface for linking together two spaces. Each of these spaces encloses its own separate clean air environment.

The interface has interlocking doors on each space which fit together to trap particles, that is, particles which have accumulated from the dirty ambient environment on the outer surfaces of the doors.

U.S. Patent Number 4,534,389 to Barclay J. Tullis for INTERLOCKING DOOR LATCH FOR DOCKABLE INTERFACE FOR INTEGRATED CIRCUIT describes a particle-free dockable interface with an interlocking latch for linking together two spaces each enclosing a clean air environment. The dockable interface prevents the opening of the interface doors without the presences of two mating system components.

The interface has interlocking doors on each space which fit together to trap particles which have accumulated from the dirty ambient environment on the outer surfaces of the doors.

The interlocking latch has a latch spring and latch foot assembly coupled to a first one of the two clean air spaces and a mating door pull and port latch assembly coupled to the second of the two clean air spaces. The latch foot, door pull, and port latch assemblies are constructed so that the interlock doors cannot be opened unless the first and second clean air spaces are properly aligned and mated.

U.S. Patent Number 4,532,970 to Mark E. Johnston, Mihir Parikh, David J. Thrasher, and Barclay J. Tullis for PARTICLE-FREE DOCKABLE INTERFACE FOR INTEGRATED CIRCUIT PROCESSING describes a particle-free dockable interface for linking together two spaces each enclosing a clean air environment. The interface is composed of interlocking doors on each space which fit together to trap particles which have accumulated from the dirty ambient environment on the outer surfaces of the doors.

U.S. Patent Number 4,859,137 to Anthony C. Bonora and Fred T. Rosenquist for APPARATUS FOR TRANSPORTING A HOLDER BETWEEN A PORT OPENING OF A STANDARDIZED MECHANICAL INTERFACE SYSTEM AND A LOADING AND UNLOADING STATION describes apparatus for transporting workpieces, as wafer cas-

ettes, between a port opening of a work station and an inter-station transporter.

The apparatus includes a first platform for supporting the cassette between the port opening and the work station; an elevator for moving the first platform between the port opening and the work station; and an assembly for rotatably moving the first platform between a first position in which the first platform is oriented substantially perpendicular to a vertical axis and a second position in which the first platform is inclined relative to the vertical axis.

The assembly moves the first platform between the first and second positions while the elevator moves the first platform between the port opening and the work station.

U.S. Patent 4,923,353 to John S. Bailey, D.R. Gunawardena, Ulrich Kaempf, and Barclay J. Tullis for APPARATUS FOR AUTOMATED CASSETTE HANDLING (Division of U. S. Patent No. 4,705,444) describes an automated cassette handler used to transport IC wafer cassettes between first and second elevators in a standardized mechanical interface (SMIF) system for integrated circuit processing. The handler is adapted to grip and transport the cassette while positively pushing the wafers into the cassette.

U.S. Patent Number 4,901,011 to Hisashi Koike and Sumi Tanaka for CARRIER FOR TRANSFERRING PLATE-LIKE OBJECTS ONE BY ONE, A HANDLING APPARATUS FOR LOADING OR UNLOADING THE CARRIER, AND A WAFER PROBING MACHINE FITTED WITH THE HANDLING APPARATUS FOR THE WAFER CARRIER describes a carrier for transferring individual semiconductor wafers. The carrier includes a tray portion to load the wafer for processing. The tray portion has a groove for unloading the wafer, and a mechanism for positioning the tray portion relative to a predetermined location of the drawer. A handling apparatus for the carrier includes a sampling case mounted to the frame of a wafer probing machine and having (i) a first opening communicating with the outside of the machine and (ii) a second opening communicating with the interior of the machine, (iii) a drawer adapted to go into and come out of the case through the first opening (i, above) and plural pairs of guide-rollers to guide the drawer between the first and second openings of the case. To take a sample from among the wafers in the machine, the carrier is loaded on the drawer, and pushed through the second opening into the case, where the wafer is then picked out by a full-automatic transferring apparatus from a wafer storage. The wafer is then inserted through the second opening into the case, and placed on the carrier by guiding it through the groove of the carrier and the drawer is pulled out.

U.S. Patent No. 4,875,825 to John S. Bailey, D.R. Gunawardena, Ulrich Kaempf, and Barclay J. Tullis, for METHOD FOR AUTOMATED CASSETTE HANDLING (Continuation of U.S. Patent No. 4,705,444), describes an automated cassette handler transporting an IC wafer cassette between first and second elevators in a standardized mechanical interface (smif) system for integrated circuit processing. The handler grips and transports the cassette while positively pushing the wafers into the cassette.

U.S. Patent No. 4,802,809 to Anthony C. Bonora, and Andrew W. O'Sullivan for MANIPULATOR FOR STANDARD MECHANICAL INTERFACE APPARATUS (Continuation In Part of U.S. Patent 4,676,709 and of U.S. Patent 4,674,936), describes an apparatus for transferring an IC wafer cassette to and from a container supported at a processing station. The processing station has a cassette port for receiving the cassette when the cassette moves along a central axis extending from outside the processing station through the cassette port, and into the processing station.

The apparatus includes (i) a transportable cassette platform for transferring the cassette to and from the container; (ii) a manipulator having (a) a first member extending substantially orthogonal to the central axis of movement of the cassette platform and (b) a movable second portion; (iii) a pivoting arm with (a) a pivoting portion and (b) a coupling portion, where the pivoting portion mounted pivotally adjacent to the movable second portion (ii-b) of the first member(ii). The pivoting arm (iii-b) is operable to pivot about a pivot axis extending substantially through the pivoting portion and substantially perpendicular to the central axis of the cassette platform. A coupling device is mounted on the coupling portion (iii-a) of the pivoting arm for coupling to the cassette. A tilt device tilts the coupling device and the cassette coupled to it during pivoting by the pivoting arm, so that during the pivoting the cassette tilts relative to the central axis.

U.S. Patent No. 4,705,444 to John S. Bailey, D.R. Gunawardena, Ulrich Kaempf, and Barclay J. Tullis for APPARATUS FOR AUTOMATED CASSETTE HANDLING describes an automated cassette handler for transporting an IC wafer cassette containing integrated circuit wafers between first and second elevators in a standardized mechanical interface (smif) system for integrated circuit processing. The handler is adapted to grip and transport the cassette while positively pushing the wafers into the cassette.

U.S. Patent No. 4,676,709 to Anthony C. Bonora and Andrew W. O'Sullivan for LONG ARM MANIPULATOR FOR STANDARD MECHANICAL INTERFACE APPARATUS describes a manipulator

for removing a cassette holding work pieces to be processed, such as semiconductor wafers, from a container supported on a processing station in a standard mechanical interface (smif) system. The container is supported on an interface port on the canopy of the processing station and has a removable door on which the cassette is supportable. A first platform is transportable along a shaft below the interface port and is operable to mate with the interface port and receive the cassette from the container. The first platform is transported down the shaft, thereby removing the cassette from the container. A second platform mounted in the shaft includes a manipulator arm which swings to engage the cassette on the first platform and support the cassette off of the first platform. The manipulator arm then pivots to transport the cassette to a location in the processing station away from the shaft. The first platform is then transported back up the shaft to the interface port to seal the container to prevent particulate contamination. The manipulator arm and the second platform after placing the cassette at a location in the processing station away from the shaft, are then positioned completely inside the shaft to minimize the space taken up in the processing station by the manipulator.

U.S. Patent 4,674,936 to Anthony C. Bonora for SHORT ARM MANIPULATOR FOR STANDARD MECHANICAL INTERFACE APPARATUS describes a manipulator for removing a cassette holding workpieces to be processed, such as semiconductor wafers, from a container supported on a processing station in a standard mechanical interface (smif) system. The container is supported on an interface port on the canopy of the processing station. A first platform is transportable along a shaft below the interface port. The platform is operable to mate with the interface port and receive the cassette from the container. The first platform is transported down the shaft, thereby removing the cassette from the container. an arm orthogonal to the shaft and mounted in the shaft supports a pivoting arm which swings to engage the cassette on the first platform and support the cassette off of the first platform. The pivoting arm pivots to transport the cassette to a location away from the shaft. The first platform is then transported back up the shaft to the interface port to seal the container to prevent particulate contamination. The pivot arm then pivots to swing the cassette to a host elevator which is located in alignment with the shaft below the first platform.

U.S. Patent No. 4,636,128 to Thomas C. Bimer, Alton D. Lewis, and Edwin G. Millis for SEMICONDUCTOR SLICE CASSETTE TRANSPORT UNIT describes a transport mechanism for transporting an IC wafer cassette between a clean carrier and a process machine. The transport unit has a housing

having a forward portion positioned in the people-occupied area of the clean room and a rear portion positioned in the process machine area, and aerodynamically isolated from people. A moveable glider plate is adapted to receive the carrier. This moveable glider plate is initially positioned in an aperture provided in the upper surface of forward portion of the transporter. A gearing mechanism is provided which cooperates with glider plate to move the IC wafer cassettes mounted on the base of carrier between the forward portion and the rear portion of the carrier. The wafers are shielded from particulate contamination both (1) as the wafer cassette is transported on the glider plate between the forward and rear portions of the transporter and (2) when evacuating any particulate contamination generated within the transport mechanism.

U.S. Patent No. 4,343,584 to Jerry Hudgins for APPARATUS FOR SEQUENTIALLY TRANSPORTING CONTAINERS describes an apparatus for transferring and manipulating a plurality of containers in a sequence. The apparatus includes a mechanical manipulator arm having a gripping device which automatically picks up a container at a fixed pickup position and transfers it to a processing station. At the processing station, the container is loaded with silicon wafers and returned by the arm to the fixed position (the initial pickup station). A plurality of the containers may be processed in sequence from the fixed pickup position by providing a movable carriage upon which container pedestal platforms are supported. At least one of the container pedestal platforms is an elevator platform.

The platforms include abutments for properly positioning the containers for accurate pickup by the manipulator arm. Sensing switches may be provided for sensing movements of the arm, the carriage, and the elevator platform. In this way the entire apparatus may be controlled automatically. This avoids the need to handle the wafers manually, reducing the possibility of contamination.

U.S. Patent No. 4,851,018 to Henri Cortial and Jean-Pierre Lazzari for INSTALLATION FOR THE STORAGE AND TRANSFER OF OBJECTS IN A VERY CLEAN ATMOSPHERE describes a system including (1) a cabinet for storing workpieces, (2) apparatus for processing these workpieces, and (3) apparatus for transferring these workpieces between the storage cabinet and processing apparatus. The transfer is carried out through mobile containers and fixed containers fixed to the processing apparatus.

The mobile containers can be coupled to the cabinet and to the fixed containers in order to carry out the transfer of the workpieces.

U.S. Patent No. 4,781,511 to Hiroshi Harada, Tsutomu Ishida, Yoshiyuki Iwasawa, and Shintaro

Kobayashi for SEMICONDUCTOR PROCESSING SYSTEM describes a semiconductor processing system which includes: (1) a first semiconductor wafer cassette for housing semiconductor wafers; (2) a first transfer pod for enclosing the first cassette airtightly; (3) wafer processing equipment having a first port for loading the cassette and a canopy covering the first port; and (4) a first mechanism for transferring the first cassette between the first port of the processing equipment and the first pod without exposing the cassette and the wafers therein to outside contamination.

The first transfer pod has a box-like pod body with an open bottom and a bottom plate detachably attached to the pod body for closing the bottom of the pod body.

The first transferring mechanism includes: a second port, provided on the canopy of the processing equipment at the position directly above the first port, for placing the first pod on the second port. The second port includes a port assembly for attaching and detaching the bottom plate of the first pod to and from the pod body when the first pod is placed on the second port. The transferring mechanism also includes a first lift mechanism, arranged mainly between the first and second ports, for conveying the bottom plate of the first pod between the first and second ports when the bottom plate of the pod is detached from the pod body.

The processing equipment processes wafers in the first cassette when the cassette is loaded in the first port.

The SMIF solution, while adequate for wafer processing, including batch processing of cassettes of large semiconductor wafers, e.g., wafers of up to about 0.127 m (about 5 inches) in diameter, is not directly applicable to panel fabrication. This is because panels are far larger, the smallest panels having at least ten times the surface area of the largest wafers. Moreover, the individual layers making up the finished thin panels are flexible films, e.g., flexible and flimsy polymeric films, including copper foiling bearing polymeric films, less than 2.54×10^{-4} m (0.01 inch) thick. For these reasons, wafer processing techniques are not directly applicable to panel fabrication.

It is a primary object of the invention to provide clean room environments for panel processing and fabrication.

It is a further object of the invention to isolate the panels in-process from human generated sources of contamination.

It is a further object of the invention to provide a clean room environment of Class-100 air for panel processing and fabrication for panel processing and fabrication in close proximity to the actual panel processing and fabrication.

It is a still further object of the invention to maintain clean room conditions during interprocess transfer between pairs of process enclosures.

These and other objects of the invention are accomplished by the method and apparatus of the present invention.

Specifically, the invention described herein utilizes isolated islands of clean room grade air to provide assured cleanliness. This is accomplished even in the event of external transients and disturbances.

The apparatus of the invention provides a clean room environment without a clean room. The clean room environment is provided in close proximity to the in-process circuit cards and boards. More particularly, the clean room environment is provided in islands or enclosures of clean room grade, substantially contaminant free, air. By this expedient it is possible to avoid the expense and difficulty of providing a large cubic foot clean room, with clean room conditions tens of feet away from the nearest card or board. Significantly relaxed, operator friendly, clean room standards are maintained in the rest of the process area.

The method and apparatus of the invention isolates panels, cards and boards in-process from human generated contamination, such as hair, skin, and breath, and isolates the work space and its environment through dedicated work space enclosures that direct clean air, e.g., Class-100 air, into the process equipment enclosures through carefully engineered and focused Class-100 air handling equipment.

According to the invention, Class-100 standards are attained and maintained in proximity to the in-process cards, boards, and panels, rather than just at the ceiling of the clean room. This is accomplished by partitioning large volume panel, board, and card fabrication facilities into smaller volumes. These smaller volumes permit precise monitoring and control of the card and board fabrication environment. Moreover, separating the "human side" of the facility from the "clean side" of the process minimizes human borne sources of contamination.

Partitioning the contaminant sensitive work pieces and process steps from the rest of the plant is accomplished through an integrated system of process equipment containing process enclosures of controlled atmosphere, dustproof transporter boxes, and airlock and material handling interfaces between the process equipment process enclosures and the transporter boxes.

1. Process Equipment Enclosures.

The equipment, such as process equipment, necessary to perform a step or set of steps of a

manufacturing process are housed in individual work station enclosures. These enclosures have dedicated engineered clean air flow, and, in this way, isolate the equipment and the in-process panels from the surrounding dirty air. As such, they are analogous to SMIF enclosures with built-in engineered air flow that isolate wafer processing equipment in a "clean" environment.

2. Inter-Process Transporters.

Panels, including batches of in-process panels, are transported between process equipment enclosures by inter-process transporters. These inter-process transporters are analogous to the SMIF Pod[®], a sealed wafer carrier that completely isolates the wafers from the environment between "clean" enclosures. However, the SMIF Pod[®] is used to transport cassettes of small, rigid wafers, while the inter-process transporter disclosed herein transports large, thin, flimsy, flexible panels.

This function gives rise to significantly different mechanical problems.

These dustproof inter-process transfer boxes interface with the small volume process equipment process enclosures through airlocks. The airlocks interfacing between the process equipment and the transporter boxes, have linear dimensions that are also several orders of magnitude greater than those encountered in SMIF wafer handling equipment.

The transporter container carries the circuit panels between substantially contaminant free environments in a substantially contaminant free environment. The container is a walled container having a pair of parallel side walls, a pair of parallel end walls, a top, and a bottom. The container is fabricated of a substantially particulate free, unfilled, polycarbonate to avoid introduction of filler materials into the clean room environment of the process enclosures or the transfer container.

One of the end walls is an access wall having an opening surrounded by a ferromagnetic gasket. The end wall and gasket are intended to receive a ferromagnetic door panel. Each of the side walls has co-planar bracket pairs for holding circuit panels.

These dustproof inter-process transfer boxes interface with the small volume process equipment process enclosures through airlocks. The airlocks interfacing between the process equipment and the transporter boxes, have linear dimensions that are also several orders of magnitude greater than those encountered in SMIF wafer handling equipment.

3. Transporter-Enclosure Transfer Mechanisms.

While the transfer mechanism appears to be analogous to the SMIF Arm^(R) robotic mechanism

which is the automatic transfer mechanism that removes wafer cassettes from the SMIF Pods^(R) and places them on the indexing means within the SMIF enclosures, the transfer mechanism described herein works with larger, flexible, flimsy, non-rigid work pieces. The transfer mechanism transfers the large, non-rigid, flimsy, flexible in-process panels, cards, and boards from the transfer container to the process enclosure, and from the process enclosure to the transfer container.

4. Panel Carrier

The interprocess transporter and the transporter-enclosure transfer mechanism are related through the vacuum loading chuck and fixture.

The panel carrier, and its associated vacuum loading chuck and fixture are an integrated system for handling large area, flimsy, in-process, circuit panel layers. The elements of the system are a peripheral frame fixture for surrounding the panel layer, and a loading chuck for mounting the panel layer in the peripheral frame fixture.

The peripheral frame fixture for surrounding the panel layer includes a bottom plate having a central opening, a top frame having a central opening, and compressive means for applying a z-axis compressive force to the bottom plate, the top frame, and the panel layer between plate and the frame. The bottom plate and top frame apply both a z-axis compressive force on the surfaces of the panel layer and x-y axis tensile forces to the panel.

The loading chuck for mounting the panel layer in the peripheral frame fixture has a peripheral edge for receiving the bottom plate of the peripheral frame fixture, and a vacuum table within the area bounded by the peripheral edge of the loading chuck and the peripheral frame of the peripheral frame fixture. The loading chuck is substantially coplanar with the panel layer. The vacuum table includes a plurality of slidable bearing surfaces. The bearing surfaces having vacuum apertures for drawing a vacuum to hold a panel against the bearing surface. The vacuum table also includes slide actuators for moving the slidable bearing surfaces to apply x-y-axis tension to a panel on the bearing surfaces. A further aspect of the vacuum table are the vacuum holes for applying a vacuum to the slidable bearing surfaces.

5. Interprocess Interlock

The transporter-enclosure transfer mechanism works in combination with an interlock which serves to maintain clean room conditions during panel transfer between the transporter and the enclosure. Thus, according to the invention described herein

the process enclosure and the inter-process transfer container have an interlock for transferring panels, for example, in-process panels, without breaking clean room conditions. The interlock starts with facing sealable doors in the process enclosure and the transfer container.

The sealable doors are in air sealable facing recesses of the process enclosure and the transfer container. At least one peripheral gasket surrounds the recesses and the pair of doors to provide a substantially clean room environment in the airlock. The sealable door in the process enclosure is moved by a controllable electromagnetic clamp. This clamp clamps the ferromagnetic transfer container door. There is a ferromagnetic gasket between the sealable, ferromagnetic door in the inter-process transfer container and the process container. This provides a magnetic seal between the ferromagnetic door of the interprocess transfer container and the ferromagnetic door thereof.

Upon actuation, the electromagnetic clamp in the process enclosure door magnetically attracts the transfer container's ferromagnetic door and pulls it away from the ferromagnetic gasket. After the ferromagnetic door is clamped by the electromagnet, the process container door and the transfer container door are simultaneously opened.

6. Robotics and Computer Integration.

The card carrier provides logistic control and tracking of in-process panels, cards, and boards. This allows increased throughput with reduced inventories. Robotic control of the panel carrying process, including the inter-process transfer boxes and the transporter to process enclosure transfer system, especially when combined with computer integrated manufacturing (CIM) real time management, provides an information interface between the panels in-process and the individual work stations.

For example, the airlock activation, which is necessary for transferring in-process panels, cards, and boards, becomes an identifiable control event. This event initiates identification of both the panel carrier and the panels to a specific manufacturing step. In turn, the identification of a particular batch of panels at a specific work station initiates a sequence of steps within the work station environment. This sequence of steps can then be used to adaptively control downstream manufacturing steps in downstream work station environments. By this expedient work in-process tracking is combined with localized process control.

Robotic control can be used in processing thin, flimsy, fixtured panels. For example, according to the invention, the fixture, including the thin panel, is placed in an air tight transfer container which has a

substantially contaminant free atmosphere, and a sealed door at one end. The transfer container is brought into a sealable, substantially airtight interlock with a process enclosure. The process enclosure also has a substantially contaminant free atmosphere, and a sealed door at one end. Airtightness can be sensed by detectors, or by an operator.

An airtight seal is formed between the transfer container and the process enclosure, and the surfaces of the two doors are isolated so as to avoid introducing surface contaminants into the process enclosure and transfer container atmospheres. The doors are then simultaneously opened by robotic action.

After the doors are opened, at least one panel and its fixture are robotically transferred from the transfer container into the process enclosure. The panel is robotically transferred to a process station inside the process enclosure, and processed. After processing, the panel and its fixture are robotically transferred from the process enclosure into the transfer container. The doors of the process enclosure and the transfer container are then closed, and the transfer container removed.

The method and apparatus of the invention is, therefore, more than just a "Scale Up" of SMIF technology. The method and apparatus of the invention utilizes (1) small gas volume, multi-work station enclosures for processing flexible, large surface area panels, cards, and boards, with (2) minimum volume, dustproof transfer containers for storing, transferring, and handling panels, cards and boards, (3) tools for transferring the in-process panels, cards and boards between individual transfer containers and the work stations, (4) fixtures to hold the large, flexible in-process panels, and (5) computer integration of the process steps and apparatus.

The invention can be understood by reference to the figures shown below.

FIGURE 1 is a general system overview showing a plurality of process enclosures. Each of the process enclosures has one or more contained process stations, a robotic unit, and a docking interlock for docking with a panel transfer container.

FIGURE 2 is a partial cutaway view of a single process enclosure, showing individual process stations therein and the robotic unit.

FIGURE 3 is a top view, in cutaway, of a single process enclosure, showing the robotic arm and the panel transfer container.

FIGURE 4 is a side elevation, also in cutaway, of the single process enclosure shown in FIGURE 3, showing the robotic arm and the panel transfer container.

FIGURE 5, including FIGURES 5a, 5b, 5c, 5d, 5e, and 5f, shows a panel, a fixture for carrying the

panel through the manufacturing processes, a chuck for assembling the fixture and the panel, and an assembly sequence for assembling the panel and the fixture.

FIGURE 6, including FIGURES 6a, 6b, and 6c, shows a perspective view of the transfer container, used for transporting panels to and between process enclosures in clean room conditions. The sequence, FIGURES 6a, 6b, and 6c, shows an open container, and the relationship of the ferromagnetic door of the container to the container.

FIGURE 7, including FIGURES 7a, 7b, and 7c, shows a perspective view of the docking interface of the process enclosure, and the sequence of steps to electromagnetically draw the ferromagnetic door of the transfer container against the electromagnetic equipped door of the docking interface, and then robotically open the door of the docking interface container.

FIGURE 8 shows the opposite surface of the door of the docking interface, including the attachment point for the robotic arm, and the electromagnets.

FIGURE 9, including FIGURES 9a, 9b, and 9c, shows a cutaway view, along cutting plane 9'-9" of FIGURE 6a, of the docking structure of the docking interface of the process enclosure and the transfer container.

FIGURE 10 is a cutaway view of a transfer container showing shelves and brackets for carrying in-process panels.

FIGURE 11 is a process flow chart for the integrated process of the system.

The integrated process and system for handling in-process panels, cards and boards includes:

- * Localized, sealed clean-room enclosures for process equipment. These sealed enclosures contain process equipment stations in a highly localized and contained, clean room environment.
- * Minimum volume, dustproof containers for transferring, storing, and handling cards and boards. These transfer containers are several magnitudes greater in volume than SMIF boxes for wafers. These transfer containers have clean room capability, and are fabricated of materials of construction that are relatively free of sources of contamination. Exemplary materials are unfilled, transparent polycarbonates. This is because fillers are a source of particulates. Preferably the transfer containers are transparent. This makes it easier for the operator to align the doors at the dockable interface with the equipment enclosure, and also to handle in-process panels inside and during docking.
- * Mating airlocks at the interface between the process equipment enclosures and at the

transfer containers, where linear dimensions of the airlocks are several orders of magnitude greater than those required for wafer handling equipment.

- * Transfer arm means for transferring the in-process panels between the transfer containers and the process enclosures.
- * Jigs and tools for holding the large, non-rigid in-process during transfer.
- * Computer monitoring and integration of the in-process panels, the process sequences and steps, and the total process.

A system overview is shown in FIGURE 1. The overall system 1, is shown with three robotic process enclosures 11a, 11b, and 11c. It is, of course, to be understood that there may be a series of such stations. The clean room atmosphere within each process enclosure is maintained by air lines or manifolds 13 bringing Class 100 or cleaner air, to each process enclosure 11a, 11b, 11c. In the FIGURE a common header 13, with individual lines 15, to each process enclosure 11a, 11b, and 11c, is shown. It is, of course, to be understood that each process enclosure 11a, 11b, 11c, may have a dedicated air line. Air is removed through exhaust header or manifold 17.

In a still further embodiment of the invention a pressurized ceiling plenum may carry Class-100 or cleaner air to all of the enclosures. In this alternative embodiment, the enclosures extend to the ceiling hepafilters (high efficiency particulate filters) in the ceiling.

The gas returns, shown in FIGURE 1 as a header or manifold 17, can extend from the process enclosure 11 out to the room, or the gas can be ducted back for further filtering and reuse, or even exhausted.

Each process enclosure 11 has one or more process stations 21a, 21b, 21c, 21d, 21e, and 21f contained therein. Typically, each process enclosure can be dedicated to a sequential set of process steps, and each process station 21 within a process enclosure 11 and each process station therein is dedicated to an individual process or step in the fabrication of panels. These steps may be under real time, on-line process control, as robotic steps. Alternatively, they may be under operator control, as through glove boxes, vision systems, and the like. For example, processes such as mechanical drilling, punch pressing, laser drilling, seeding, plating, etching, photoresist deposition, photoresist exposure, photoresist developing, and photoresist stripping can be carried out without operator intervention. However, processes such as alignment, lamination, bonding and the like can also be carried out in the process stations 21, but, possibly with operator intervention.

A set of process stations, for example sequential process stations 21a and 21b, or 21c and 21d, or 21e and 21f, are incorporated into and communicate through individual process enclosures, as 11a, 11b, or 11c. This reduces the opportunities for inadvertent exposure to the ambient environment.

An individual process station, as process station 21a, may be designed for wet processes, with process piping 23a and 23a'. Alternatively, an individual process station, as process stations 21c, 21d, and 21e, may be adapted for other processes, as testing and repair of circuit lines, photo-resist deposition, photolithography (including dry side exposure or wet side developing or stripping).

Process stations, as process station 21d may be glove boxes, with gloves 25 extending therefrom for intervention and treatment of panels. This is especially true for process requiring an operator, as alignment, lamination, or bonding.

The process stations 21 and the processes contained therein may be controlled by various means. FIGURE 1 shows a personal computer or work station 51, communicating with the process enclosures 11, and with the individual process stations 21a, 21b, 21c, 21d, 21e, 21f, and the processes contained therein, through local area network means 53. The extent of control may be as simple as job sequencing, or as involved as work in process identification, with work piece identification indicia (for example bar coded work piece indicia or magnetic strip work piece indicia), control of photomasks, drill patterns, sequences of process stations, and the like.

Within each process enclosure 11, inter-process transfer is provided without breaking clean room integrity. This is accomplished through the use of robotic transfer means, as shown in FIGURES 2, 3, and 4. FIGURE 2 is a representation of one form of a SCARA (Selective Compliant Assembly Robot Arm) robot 61 within a process enclosure 11, while FIGURES 3 and 4 are top and plan views of an alternative form of a SCARA robot. The same numbering is used in FIGURE 2 and in FIGURES 3 and 4.

In FIGURE 2 the robot system 61 is shown inside of the process enclosure 11, with process stations 21a and 21b. In FIGURES 2, 3, and 4, the robot system 61 includes the SCARA robot, 63; a bar code scanner, 65; a wet frame and tray grabber, 67; a vacuum grabber, 69, for substrates; a process enclosure box door grabber 71; and a screw driver 73. The effector arm of the SCARA robot also includes a quick change wrist 81.

The flexible in-process panels 100 are carried by a fixture 171, shown in FIGURE 5, including FIGURES 5a, 5b, 5c, 5d, 5e, and 5f. The fixture is part of a multi-component system, including a vacuum loading chuck 121 and the two-part fixture

171. The two part fixture includes a bottom plate 175 and a frame 179.

In order to avoid abrasion and resultant contamination, the vacuum loading chuck 121 and the fixture 171 are made of PTFE coated metal. This minimizes particulate generation and possible damage to the panels. The chuck 121 has four bearing surfaces, 131a, 131b, 131c, and 131d. These four bearing surfaces 131a, 131b, 131c, and 131d, are connected by slide actuators. Vacuum holes 133a, 133b, 133c, and 133d are shown in the figure. These vacuum holes are in the top surfaces of the four bearing surfaces 131a, 131b, 131c, and 131d. These vacuum holes 133a, 133b, 133c, and 133d allow a vacuum to be drawn on the underside of the card, board, or panel, holding it flat against the bearing surfaces 131a, 131b, 131c, and 131d.

The peripheral edges 125 of the vacuum loading chuck 121 are recessed below the plane of the tops of the bearing surfaces 131, such that the bottom surface of the fixture 171 will fit onto the recessed surface 125 of the vacuum loading chuck 121.

The workpiece, as an in-process printed circuit board, or a single layer thereof, is laid on the loading chuck 121, and located by locating pins. A vacuum is then applied to the under surface of the work piece 100 through the vacuum holes 133a, 133b, 133c, and 133d, and tension is applied to the work piece by diagonal motion of each of the bearing surfaces 131a, 131b, 131c, and 131d, of the vacuum loading chuck 121 away from the central portion of the chuck. The amount of tension is easily adjustable by the operator or by numerical control methods.

Once suitable tension in the workpiece 100 is achieved, the top piece 179 of the fixture 171, a work piece frame, is positioned over the bottom plate 175 of the fixture 171 and lowered into place. Guide pins 181a, 181b, 181c, and 181d, on the bottom portion 175 of the fixture 171 provide centering of the workpiece 100 and the top or work piece frame portion 179 of the fixture 171 with the bottom plate of the fixture. A plurality of fasteners 183 are used to secure the top of work piece frame portion 179 of the fixture 171 to the bottom plate portion 175 of the fixture 171.

Tension in the panel (which may be as thin as 25 μm (1 mil) is generated by the motion of the four bearing surfaces 131a, 131b, 131c, and 131d, of the vacuum loading chuck 121. This tension is readily maintained by the compression of the work piece frame 179 of the fixture 171 and the bottom plate 175 of the fixture 171 on the workpiece 100.

The loading of a workpiece 100, such as a card, board, or panel 100, into a fixture 171 and the removal of the workpiece 100, such as a board, card, or panel 100 from the fixture 171 can be

done robotically, in clean room conditions. In the robotic alternative, the robot end effectors would be a flexible gripper, a screw driver, and a vacuum loading chuck to hold the individual panels.

Precision alignment of the panels is not required. The fixture 171 need only provide coarse alignment; a separate vision system is used to do fine alignment utilizing registration fiducials.

This vision system utilizes either or both of the top frame 179 or bottom plate 175 of the fixture 171, which are provided with indicia, such as bar code, for computer identification and control purposes.

The interface between the localized, clean room environment of the individual process enclosure 11 and the inter process transfer container 101 is provided by an airlock transfer port. The airlock transfer port utilizes a combination of (1) co-operating sealable doors in the process enclosure 11 and the transfer container 101, (2) electromagnetic and ferromagnetic clamping means for simultaneously opening the doors, and (3) peripheral gaskets surrounding the pair of doors to provide a substantially clean room environment in the airlock. This interface is illustrated in FIGURES 6 through 9.

FIGURES 6 through 9 show the docking of the transfer container 101 and the process enclosure 11 at the mechanical docking interface 301 (Figs. 3 and 4) in detail.

The mechanical interface 301 (Figs. 3 and 4) is designed such that the box is loaded onto a shelf with guide surfaces 311a, 311b for location control.

A latch mechanism 211 secures the transfer container 101 to the interface 301 and prevents accidental removal during the robotic loading and unloading.

The interface mechanism 301 of the transfer container 101 and the process enclosure 11 has a pair of sealed doors 31 and 131 to prevent particles from the non-clean, external environment from entering the process enclosure 11. Particles on the outside of the sealed doors 31 and 131 of the process enclosure and the transfer container 101 are trapped between the two doors 31 and 131 of the process enclosure 11 and the transfer container 101 when the transfer container 101 is locked in place on the shelf 311, compressing the various gaskets and seals 35, 37, and 133.

FIGURE 6, including FIGURES 6a, 6b, and 6c, shows a perspective view of the transfer container, 101, used for transporting panels 100 to and between process enclosures 11 in clean room conditions. FIGURE 6a shows an empty transfer container 101 having an opening, 103, i.e., an airlock opening, in its front surface. To be noted is that the transfer container 101 has a circumferential leading edge 105, encircling the airlock, and adapted for

co-operating with a facing gasket 33 on the airlock transfer port 30 of the process enclosure 11, and compressing the gasket 33 to form an airtight seal therebetween (Fig. 7).

Within the transfer container 101 and recessed from, non-coplanar with, and substantially parallel to the leading edge 105 of the transfer container 101 is an elastomeric, deformable ferromagnetic gasket 133 (i.e., a "ferromagnetic gasket"). The ferromagnetic gasket 133 is of the type typically used in freezers and refrigerators. The ferromagnetic is adapted to receive and magnetically hold a ferromagnetic door 131 over the opening 103 in the front of the transfer container 101.

The sequence, FIGURES 6a, 6b, and 6c, illustrates an open interprocess transfer container 101, and the relationship of the ferromagnetic door 131 of the container 101 to the container 101. FIGURE 6a shows the interprocess transfer container 101 with a ferromagnetic door 131 spaced therefrom. FIGURE 6b shows the ferromagnetic door panel 131 being pulled away from the interprocess transfer container 101, opening the front opening thereof.

FIGURE 7, including FIGURES 7a, 7b, and 7c, shows a perspective view of the docking interface 30 of the process enclosure 11, and the sequence of steps to electromagnetically draw the ferromagnetic door 131 of the transfer container 101 away from the interprocess transfer container 101 and against the electromagnet 37 equipped door 31 of the process enclosure 11 at its docking interface 301, and then robotically open the magnetically coupled doors, 31 and 131, of the process enclosure 11 docking interface 301 and the interprocess transfer container 101.

FIGURE 7a shows the process enclosure port 30, with a pair of circumferential gaskets, 33 and 35, a sealable door, 31, and one or more electromagnets, 37. FIGURE 7b shows the interprocess transfer container 101 in phantom, pressing against the process enclosure 11 port. The ferromagnetic door 131 of the interprocess transfer port 301 is shown partially broken away, with the electromagnet 37 and a portion of the inner circumferential gasket shown.

FIGURE 7c shows the interprocess transfer container 11 and the process enclosure 11 port 301, with the ferromagnetic door 131 of the interprocess transfer container 11 and the electromagnetic door 31 of the process enclosure 11 partially drawn into the process enclosure 11 interlock. The open airlock provides the means for transferring panels between the transfer container 101 and the process enclosure 11.

To be noted is the inner gasket 35. This inner gasket provides a seal between the major portion of the areas of each of the doors, 31 and 131, and

the interior of the process enclosure 11. In this way the gasket keeps surface dirt on the door surfaces from contaminating the localized clean room atmospheres of the process enclosure 11 and the interprocess transfer container 101.

FIGURE 8 shows the opposite surface of the door 31 of the docking interface, 301, including the attachment point 81 for the robotic arm 63, and the electromagnets, 37.

FIGURE 8 shows the interprocess transfer container 101 abutting the facing segment of the process enclosure 11, with the outer gasket 33 of the interface dock 301 providing a compressive seal therebetween. This seal isolates the clean room atmospheres of the interprocess transfer container 101 and the process enclosure 11 from contaminated outside air. The inner gasket 35 between the two movable doors 31 and 131 is also shown.

The two doors 31 and 131 are initially in contact and both closed. Compressive means are used to provide the compressive seals between the (1) the outer gasket 33 and the leading edge 105 of the interprocess transfer container 101, and (2) the inner gasket 35 and the ferromagnetic door 131 of the interprocess transfer container 101. After the compressive seals are established, the electromagnet or electromagnets 37 are activated, to break the ferromagnetic and hermetic seals between the ferromagnetic gasket 33 and the ferromagnetic door 131 and magnetically clamp the doors together. The robotic arm 63 then draws the process enclosure door 31 into the process enclosure 11. The robotic arm 63 carries the two doors 31 and 131 into the process enclosure 11 to provide an unobstructed channel for moving the panels between the process enclosure 11 and the interprocess transfer container 101.

The numerical control means 51 for the robotic effector 63 and the electromagnets 37 properly sequences the operation of opening the doors 31 and 131 to avoid contamination of the localized clean room environments, isolating surface contamination in the volume surrounded by the inner gasket 35 between the two doors 31 and 131.

FIGURE 9, including FIGURES 9a, 9b, and 9c, shows a cutaway view, along cutting plane 9-9 of FIGURE 6a, of the docking structure of the docking interface of the process enclosure and the transfer container.

FIGURE 9a shows mating structures of the process enclosure 11 and the interprocess transfer container 101 as they are brought into sealable contact. Specifically to be noted are the gaskets 33 and 35, with the outer gasket 33 on the periphery of the process enclosure interlock 301 and the inner gasket 35 on the process enclosure 11 door 31. The ferromagnetic seal 133 is compressed by the ferromagnetic door 131 of the interprocess

transfer container 101.

FIGURE 9b shows the two surfaces in contact, with the outer gasket 33 providing a compressive seal between the facing walls 39 and 105 of the process enclosure 11 and the interprocess transfer container 101. The inner gasket 35 provides a compressive seal between the door 31 of the process enclosure 11 and the ferromagnetic door 131 of the interprocess transfer container 101, sealing outside contamination therebetween.

FIGURE 9c shows the structure as the doors 31 and 131 begin to open. The seals 33 and 35 are still in place, that is, the outer gasket 33 continues to provide a compressive seal between the facing walls 39 and 105 of the process enclosure 11 and the interprocess transfer container 101 to keep outside contamination out of the clean room atmospheres. The inner gasket 35 continues to provide a compressive seal between the door 31 of the process enclosure 11 and the ferromagnetic door 131 of the interprocess transfer container 101, still sealing outside contamination between the two doors 31 and 131.

The door 31 of the process enclosure 11 is designed such that a robotic end effector 63 is used to engage both of the doors, that is, one door, the process enclosure door 31, is effected mechanically, and the other door, the interprocess transfer container door 131 is effected electromagnetically. Preferably the robotic end effector 63 and its companion magnetic effector 37 engages both of the doors 31 and 131 simultaneously. The door assembly includes keying surfaces to prevent the doors from rotating relative to the end effector 63, as well as keys and pins to prevent the doors 31 and 131 from rotating with respect to one another or otherwise misaligning.

The electromagnetic end effector 37 attracts and clamps the transfer container door 131, clamping the enclosure door 31 to the transfer container door 131, for example, by friction and magnetic force. The electromagnet 37 has sufficient magnetic force to pull the transfer container door 131 away from the ferromagnetic gasket 133. In this way one pulling motion opens both doors, 31 and 131, simultaneously.

Simultaneously opening both doors, 31 and 131, significantly reduces contaminant generation caused by the relative motion of one door part against the other door. A further advantage of opening both doors simultaneously is that particles on the outside of the transfer container door 131 and/or on the outside of the enclosure door 31 are trapped and safely contained between both doors 31 and 131 by the magnetically effected simultaneous opening of both doors.

The interprocess panel transfer container 101 provides clean room transfer of panels between

pairs of process enclosures, 11, for example, adjacent process enclosures 11. The interprocess panel transfer container or transporter 101 is characterized by being substantially free of sources of particulate contamination, the minimum volume necessary for storing and handling cards and boards, and suitable airlocks for mating with facing airlocks 31a, 31b, 31c, of the process enclosures 11a, 11b, and 11c.

In a particularly preferred embodiment of the invention the panel transfer container 101 is formed of unfilled polycarbonate. This is because fillers are a source of particulates. A further advantage of unfilled polycarbonates is that they are transparent. The use of transparent materials of construction for the panel transfer containers 101 makes the panel transfer containers 101 easier to align at the dockable interface 31. A further advantage of transparent materials of construction is that it is easier to handle foils and thin panels inside the panel transfer container, especially during docking.

The transfer container 101 (Fig. 10) is a walled container having a facing pair of parallel side walls, 107 and 109, a facing pair of parallel end walls 111 and 113, a top, 115, and a bottom, 117, fabricated of a substantially particulate free material, such as unfilled, polycarbonate. One of the end walls is an access wall having an opening surrounded by a ferromagnetic gasket 133. This ferromagnetic gasket is adapted to receive a ferromagnetic door panel 131.

Each of said side walls 107 and 109 has at least one pair of co-planar bracket pairs 119. These bracket pairs 119a and 119b hold the panels 100. The panels are in the fixtures 171 described hereinabove.

At least one bracket 119a or 119b of each bracket pair has a pyramidal or conical positioning pin 121. The positioning pin 121 extends upwardly from the bracket 119 and is adapted to receive a workpiece bracket 171. A mating aperture 191 (Fig. 5) in the fixture 171 receives the positioning pin 121.

In a preferred embodiment wherein both brackets 119a and 119b of a bracket pair have the pyramidal or conical positioning pins 121 extending upwardly and adapted to receive a workpiece fixture 171.

Various process and process sequences may be carried out using the system and method described herein. FIGURES 3 and 4 provide top and side views of the function of a robotic arm, for example, a SCARA robot 61, inside of the process enclosure. Workpieces, as printed circuit boards or individual layers thereof are placed in fixtures, as shown in FIGURE 5. These fixtures are then placed into sealable inter-process transfer containers 101 of the type shown in FIGURE 6. The box is then

purged with high quality, contaminant free gas, as 100K air, to provide an isolated storage environment of clean room quality.

At a later point, an operator selects a container 101 of panels for processing. The container is placed on the process enclosure 11 container shelf 311 (Fig. 4), in sealable relationship with the process enclosure 11. Sealable relationship is maintained by fasteners, clamps, or bolts 211 at the back of the transfer container 101. Guides in the shelf align the edges 105 (Fig. 6) of the inter-process transfer container 101 with the corresponding gasketed edges 33 of the process enclosure 11 (Fig. 7). The clamps 211 are then tightened to form the gas seal.

At this point the sequencing functions of the robot 61 are activated. For example, if a "retrieve workpieces" sequence is called, the first step is to activate an "door open" sequence. In this sequence robotic arm activates the door gripper end effector 81, and energizes the electromagnet 37 in the process enclosure door 31 to overcome the ferromagnet in the ferromagnetic gasket 133.

Both doors are secured to the robotic arm end effector 81, the process enclosure door directly, and the transfer container door 131 magnetically, and removed in one motion.

The robotic arm then releases the door gripper end effector 81 and the doors 31, 131 in a resting position inside the process enclosure 11.

Next, the robotic arm takes an end effector 67 for gripping the in-process panel fixture 171, and removes a populated panel fixture 171 from the transfer container 101. The order in which panels are removed is programmed by the operator.

The fixtures 171 or the panel layers themselves may have indicia, as part numbers, serial numbers, or the like. This may be optically coded, magnetically code, or bar coded. The robotic arm may pass the fixture 171 over a decoder 65 (Fig. 2) to read the indicia. Using this indicia, the robotic end effector performs such functions as orienting the the fixture, if necessary, and passing the fixture to a tool load station, as a roll conveyor for wet processing, or to a work station for dry processing.

The inverse of the above sequence could then be used to unload the fixture 171 and its contained panel 100 from the process enclosure 11 back into the carrier.

In another possible sequence of events the fixture gripper end effector 67 places the fixture onto a vacuum chuck 68 (Fig. 3). The vacuum is initiated, while the gripper end effector is replaced by, for example, a screw driver end effector 73. The screw driver end effector is used to remove the hold down or compressive fittings on the fixture 171. The top frame 179 of the fixture is then removed, for example by another end effector.

At this point the robotic arm may replace the screw driver or gripper end effector by a vacuum end effector 69. The vacuum chuck 68 vacuum is turned off and the vacuum end effector 69 vacuum is activated, allowing the robotic arm with the vacuum end effector to pick up the unfixtured panel 100.

The panel is then moved past a decoder, as a bar code reader, and placed in a work station for unfixtured processing.

It is, of course, to be understood that the above sequence may be carried out in reverse sequence for placing the processed panel back into the fixture 171, and then into the transfer container 101.

Various panel fabrication processes and sequences may be carried out in the apparatus of the invention, using various methods of operation. For example, as shown in the flow chart of FIGURE 11, solely by way of exemplification and illustration, and not limitation, in a subtractive circuitization process, panels with thin films of seed layer, copper, and photoresist, may be robotically taken from a transporter, through a process enclosure 11, to a first process station 21a by robotic means 61. The panel is imaged in the first process station 21a, a dry process under clean room conditions, and robotically removed therefrom by robotic means 61 from the first process station, 21a, to and through the process enclosure 11, to a second process station, 21b.

The imaged photoresist is developed in the next process station, 21b, in a wet process under clean room conditions. The developed panel is then removed from the developing process station 21b under clean room conditions and robotically transported by robotic means 61 to and through the process enclosure 11 to an etching process station 21c for wet etching, also under clean room conditions. Finally, the etched panel is robotically removed from the process station 21c by robotic means 61, and delivered to a process station 21d for removal of the remaining photoresist.

All of these process have been carried out in individual, modular process stations, under clean room conditions, but without the necessity of a large clean room.

Claims

1. A method of manufacturing a printed circuit panel comprising the steps of:

- a. providing a thin, non-rigid panel in a fixture system;
- b. placing the fixture system in an air tight transfer container (101) having a substantially contaminant free atmosphere, and a sealed door at one end;

c. bringing the transfer container into a sealable, substantially airtight interlock with a process enclosure (11) having a substantially contaminant free atmosphere, and a sealed door at one end;

d. forming an airtight seal between the transfer container (101) and the process enclosure (11);

e. forming an airtight seal between the surfaces of the two doors to avoid introducing surface contaminants into the process enclosure and transfer container atmospheres, and thereafter simultaneously opening the sealed doors of the process enclosure and the transfer container;

f. transferring at least one panel and its fixture system from the transfer container into the process enclosure;

g. transferring the at least one panel to a process station inside the process enclosure and performing a process on the panel;

h. thereafter transferring the at least one panel and its fixture system from the process enclosure into the transfer container;

g. closing the doors of the process enclosure and the transfer container.

2. The method of claim 1 further comprising:
removing the panel from the fixture system after step f.,
transferring the at least one unfixtured panel to a process station inside the process enclosure and performing a process on the unfixtured panel; and
returning the panel to the fixture system after step g.

3. The method of claim 1 further comprising electromagnetically clamping the ferromagnetic door of the transfer container to the process enclosure door, and thereafter simultaneously opening the sealed doors of the process enclosure and the transfer container.

4. A transfer container for carrying circuit panels in and between substantially contaminant free environments, especially for use in a method according to claim 1 or 2 comprising:

a. a walled container having a facing pair of parallel side walls, a facing pair of parallel end walls, a top, and a bottom, comprising a substantially particulate free, unfilled, polycarbonate;

b. one of said end walls being an access wall having an opening surrounded by a ferromagnetic gasket and adapted to receive a ferromagnetic door panel; and

c. each of said side walls having co-planar bracket pairs for holding circuit panels.

5. The transfer container of claim 4 wherein at least one bracket of a said bracket pair having a pyramidal or conical positioning pin extending upwardly therefrom and adapted to receive a workpiece. 5
6. The transfer container of claim 4 wherein both brackets of a said bracket pair have pyramidal or conical positioning pins extending upwardly therefrom and adapted to receive a workpiece. 10
7. The transfer container of any one of claims 4 to 6 wherein the side walls, and the top and bottom walls extend beyond said access wall, the ends of said walls defining a plane, and the said access wall is recessed with respect to the plane defined by the said extensions. 15
8. An airlock transfer port between a process enclosure according to claim 1 and a transfer container according to any one of claims 4 to 7 comprising: 20
 - (1) facing sealable doors in the process enclosure and the transfer container, wherein: 25
 - a. the sealable doors are in air sealable facing recesses of the process enclosure and the transfer container, with at least one peripheral gasket surrounding the recesses and the pair of doors to provide a substantially clean room environment in the airlock, 30
 - b. the sealable door in the process enclosure has controllable electromagnetic clamping means, and 35
 - c. the sealable door in the interprocess transfer container comprises a ferromagnetic material; 40
 - (2) a ferromagnetic gasket between the sealable, ferromagnetic door in the interprocess transfer container and the process container to provide a magnetic seal therebetween; 45
 - (3) means for activating the electromagnetic clamping in the process enclosure door and attracting ferromagnetic door in the interprocess transfer container away from the ferromagnetic gasket; and 50
 - (4) means for simultaneously opening the process enclosure door and the ferromagnetic interprocess transfer container door. 55
9. The airlock transfer port of claim 8 comprising second gasket means within the facing periphery of the said doors to sealably isolate, be-

tween the doors and the second gasket means, surface contamination on either of both of the doors.

10. The airlock transfer port of claim 8 or 9 comprising latch mechanism means to compress the at least one peripheral gasket surrounding the recesses and the pair of doors to provide a substantially clean room environment in the airlock and secure the interprocess transfer container to the airlock transfer port.
11. The airlock transfer port of claim any one of claims 8 to 10 wherein the process enclosure door has a robotic interface, and the transfer port comprises robotic means to sequentially first activate the electromagnet and to thereafter open the magnetically clamped doors.
12. A fixture system especially for use in a method according to claim 1 comprising:
 - a. a peripheral frame loading fixture for surrounding the panel layer, said peripheral frame loading fixture comprising:
 - i. a bottom plate having a central opening,
 - ii. a top frame having a central opening, and
 - iii. compressive means for applying a z-axis compressive force to the bottom plate, the top frame, and a panel layer therebetween,
 said bottom plate and top frame applying a z-axis compressive force on the surfaces of the panel layer and x-y-axis tensile forces to the panel during subsequent panel processing; and
 - b. a loading chuck for mounting the panel layer in the peripheral frame fixture, said loading chuck comprising:
 - i. a peripheral edge for receiving the bottom plate of the peripheral frame fixture,
 - ii. a vacuum table within the area bounded by the peripheral edge of the loading chuck and the peripheral frame of the peripheral frame fixture, and substantially coplanar therewith, for bearing the panel layer, said vacuum table comprising:
 - a. a plurality of slidable bearing surfaces, the bearing surfaces having vacuum apertures for drawing a vacuum to hold a panel against the bearing surface;
 - b. slide actuators for moving the slidable bearing surfaces to apply x-y-axis tension to a panel on the bearing surfaces; and

c. means for applying a vacuum to the slidable bearing surfaces.

13. The fixture system of claim 12 wherein the peripheral frame fixture includes alignment means for aligning the bottom plate, a panel layer, and the top frame. 5
14. The fixture system of claims 12 or 13 wherein the peripheral frame fixture includes robotic interface means for allowing a robotic arm to grasp and transfer the peripheral frame fixture. 10
15. The fixture system of any one of claims 12 to 14 wherein the loading fixture comprises vacuum header means for drawing a vacuum. 15
16. A reduced contaminant manufacturing system comprising a plurality of isolated process enclosures, with movable interprocess transfer containers for transferring workpieces therebetween, said process enclosures and interprocess transfer containers having 20
- (1) recesses adapted to face each other in gasketable, air sealable relationship; 25
 - (2) sealable doors in the gasketable, air sealable recesses of the process enclosure and the transfer container, with at least one peripheral gasket surrounding one of the recesses and doors to provide a sealed environment in the airlock for forming temporary airlocks therebetween for transfer of workpieces, 30
 - (3) controllable electromagnetic clamping means in the process enclosure door; 35
 - (4) ferromagnetic material in the interprocess transfer container door; 40
 - (5) a ferromagnetic gasket between the sealable, ferromagnetic door in the interprocess transfer container and the process container to provide a magnetic seal therebetween; 45
 - (6) means for activating the electromagnetic clamping means in the process enclosure door and attracting ferromagnetic door in the interprocess transfer container away from the ferromagnetic gasket; and 50
 - (7) means for simultaneously opening the process enclosure door and the ferromagnetic interprocess transfer container door. 55
17. The manufacturing system of claim 16 comprising second gasket means within the facing periphery of the said doors to sealably isolate, between the doors and the second gasket means, surface contamination on either of both of the doors.

18. The manufacturing system of claim 16 or 17 comprising latch mechanism means to compress the at least one peripheral gasket surrounding the recesses and the pair of doors to provide a substantially clean room environment in the airlock and secure the interprocess transfer container to the airlock transfer port.
19. The manufacturing system of claim 16 wherein the process enclosure door has a robotic interface, and the transfer port comprises robotic means to sequentially first activate the electromagnet and to thereafter open the magnetically clamped doors.
